SUMMARY
We investigate Mach wave coherence for kinematic supershear ruptures with spatially heterogeneous source parameters, embedded in 3-D scattering media. We assess Mach wave coherence considering: (1) source heterogeneities in terms of variations in slip, rise time and rupture speed; (2) small-scale heterogeneities in Earth structure, parametrized from combinations of three correlation lengths and two standard deviations (assuming von Karman power spectral density with fixed Hurst exponent); and (3) joint effects of source and medium heterogeneities. Ground-motion simulations are conducted using a generalized finite-difference method, choosing a parametrization such that the highest resolved frequency is ∼5 Hz.

We discover that Mach wave coherence is slightly diminished at near-fault distances (<10 km) due to spatially variable slip and rise time; beyond this distance the Mach wave coherence is more strongly reduced by wavefield scattering due to small-scale heterogeneities in Earth structure. Based on our numerical simulations and theoretical considerations we demonstrate that the standard deviation of medium heterogeneities controls the wavefield scattering, rather than the correlation length. In addition, we find that peak ground accelerations in the case of combined source and medium heterogeneities are consistent with empirical ground-motion prediction equations for all distances, suggesting that in nature ground-shaking amplitudes for supershear ruptures may not be elevated due to complexities in the rupture process and seismic wave scattering.

Key words: Mach wave; Kinematic rupture; 3D scattering media; Ground motion prediction equation.

1 INTRODUCTION

Seismological studies for crustal earthquakes report that the rupture front typically propagates at ∼80 per cent of the shear wave speed (e.g. Heaton 1990; Mai & Thingbaijam 2014). However, the rupture speed may exceed the shear wave speed, as shown by theoretical and observational studies. For example, by analysing strong motion records, it was shown for several earthquakes that the rupture locally propagated faster than the shear wave speed [V_s; e.g. for the 1979 M_w 6.5 Imperial Valley, California, earthquake: Olson & Apsel (1982) and Archuleta (1984); for the 1999 M_w 7.6 Izmit and M_w 7.2 Duzce, Turkey, earthquakes: Bouchon *et al.* (2001); for the 2002 M_w 7.9 Denali Fault, Alaska, earthquake: Aagaard & Heaton (2004), Dunham & Archuleta (2004) and Ellsworth *et al.* (2004)]. The analysis of seismic waveforms recorded at regional (<2000 km) or teleseismic distances demonstrated that the 2001

M_w 7.8 Kunlun, Tibet, earthquake (Walker & Shearer 2009; Vallée & Dunham 2012) and the 2013 M_w 7.5 Craig, Alaska, earthquake (Yue *et al.* 2013) also showed supershear rupture speed over parts of the fault plane. Both strong motion and teleseismic records suggest that the 2010 M_w 6.9 Qinghai, China, earthquake may have propagated at supershear speed (Wang & Mori 2012). Therefore, seismic waveforms recorded in the near-field as well as at far-field distances from different earthquakes provide evidence for the existence of supershear ruptures.

Kinematic and dynamic rupture models predict larger ground-motion amplitudes (or high frequencies) from supershear rupture compared to sub-Rayleigh rupture (e.g. Bernard & Baumont 2005; Dunham & Archuleta 2005). However, the analytical studies and dynamic rupture modelling show that a crack tip propagating at supershear speed creates a slip velocity function with reduced high-frequency content compared to the sub-Rayleigh case (Andrews

1976; Bizzarri & Spudich 2008). Additionally, Bizzarri & Spudich (2008) demonstrate that Mach cone amplification of high frequencies overwhelms the reduction of high-frequency content in slip velocity for supershear ruptures, leading to a net enhancement of high frequencies for supershear ruptures. Nevertheless, the two competing effects of dynamic reduction of high frequencies in slip velocity and large ground-motion amplitudes for supershear ruptures require further exploration.

Furthermore, Dunham & Bhat (2008) show that supershear ruptures radiate both shear and Rayleigh–Mach waves that transmit large amplitude of ground motions even to large distances from the fault. Andrews (2010) analysed ground velocities from sub-Rayleigh and supershear events for 2-D models with same fracture energy and stress drop. The directivity beam generated in the sub-Rayleigh case is concentrated in a narrow azimuth range around the fault having intense peak velocity, but attenuates as the beam diverges with increasing distance from the fault. The Mach wave from supershear ruptures forms a beam of parallel rays with constant amplitudes out to greater distances, and attenuates due to diffraction and scattering.

In addition to the above findings, Bizzarri *et al.* (2010) studied the effects of heterogeneous rupture propagation on shear and Rayleigh–Mach wave coherence for supershear ruptures on a vertical planar fault embedded in a homogeneous medium. They found that heterogeneous rupture propagation reduces peak ground velocity (PGV), but the shear and Rayleigh–Mach waves generated by supershear ruptures transmit larger ground motion much farther from the fault compared to sub-Rayleigh ruptures. They utilized strong motion records from three supershear earthquakes to validate their numerical modelling results, investigating spectral acceleration (SA) at stations that presumably experienced Mach waves during the 1979 Imperial Valley, 1999 Izmit and 2002 Denali Fault earthquakes. Comparing to SA observed at non-Mach-pulse stations for the same earthquake, they found no average elevation of SA relative to ground-motion prediction equations. This difference could arise either from the sparsity of the data (i.e. supershear ruptures do have larger ground motions, on an average, but the few records may have been biased fortuitously towards lower ground motions) or there are additional processes that reduce ground motions from supershear ruptures (e.g. loss of Mach front coherence by additional source complexity and/or scattering along the wave propagation path). The purpose of this study is to investigate the discrepancy between observations and previous studies through a set of simulations that explicitly take into account small-scale heterogeneities and the resulting wave scattering.

Mach wave observations are still limited in seismology. Either Mach waves are generally not excited because supershear rupture propagation occurs only infrequently, or Mach wave signatures are lost due to seismic-wave propagation effects. Heterogeneities present in the Earth's crust scatter seismic waves, and their impact on ground motion has been the subject of several numerical studies (Frankel & Clayton 1986; Frenje & Juhlin 2000; Pitarka & Ichinose 2009; Hartzell *et al*. 2010; Imperatori & Mai 2013; Bydlon & Dunham 2015). The effects of seismic scattering are more pronounced on S waves than P waves, and mainly distort the S-wave radiation pattern at frequencies above 2 Hz at distances relevant for seismic hazard (Pitarka & Ichinose 2009; Takemura *et al*. 2009). In addition, numerical simulations show substantial influence of medium heterogeneities on ground velocities (Hartzell *et al*. 2010) and ground accelerations (Imperatori & Mai 2013). Moreover, scattering extends the duration of incoherent high-frequency ground motion and increases the root-mean-square acceleration, at least

in 2-D (Bydlon & Dunham 2015). However, these studies focused exclusively on sub-Rayleigh ruptures embedded in heterogeneous media, and hence provide no information on ground motion radiated by supershear ruptures.

To analyse the effects of medium heterogeneity and rupture complexity on Mach wave front properties, we conduct a set of numerical experiments. We hypothesize that random heterogeneities in Earth structure and rupture complexities diminish or even destroy the coherence of Mach-waves and reduce their high frequency content. We perform ground-motion simulations using kinematic earthquake sources with specified spatio-temporal rupture evolution. The seismic wavefield is computed using a 3-D finite-difference method. Wavefield signatures as well as ground-motion parameters are then analysed with respect to Mach wave effects.

The sections of the paper are organized as follows. First, we describe the computational model geometry and analyse the effects of source heterogeneities on Mach wave properties. Next, we present the effects of medium heterogeneities on the seismic wavefield. Finally, we study the combined effects of source and medium heterogeneities on Mach wave.

2 MODEL GEOMETRY AND COMPUTATIONAL METHOD

The section describes the source and medium used as the reference case, receiver geometry and numerical method employed to compute ground motions.

2.1 Source model description

We use a kinematic source description that specifies the spatio-temporal evolution of slip in terms of a discrete set of point moment tensor sources. The heterogeneous slip distribution (D) is characterized by a von Karman autocorrelation function (Mai & Beroza 2002), parametrized by correlation lengths in the along-strike ($ax = 16$ km) and down-dip ($az = 4$ km) directions and Hurst exponent ($H = 0.75$). Our slip realizations preserve one point statistics as the complementary cumulative distribution function (CCDF) of slip exhibits truncated exponential behaviour as observed by Thingbaijam & Mai (2016). The rise time (T_r) and rupture speed (V_r) variations are obtained assuming correlation with slip based on previous studies. Dynamic rupture simulations show 50–70 per cent correlation between slip and rise time (Schmedes *et al.* 2010, 2013; Mai *et al.* 2017), however, the correlation of slip with rupture velocity is more complex. Some studies considering dynamic rupture models show that faster rupture speed correlates with areas of large slip (Oglesby & Day 2002; Guatteri *et al.* 2003), whereas other studies find little or almost no correlation between these two parameters (Schmedes *et al.* 2010; Mai *et al.* 2017). In this study, we consider 30 and 60 per cent correlation of rupture speed and rise time, respectively, with slip, consistent with values used by Liu *et al.* (2006) in their rupture generator.

Correlations among rupture parameters are developed following the theory of Gaussian random variables, similar to previous studies (Liu *et al.* 2006; Graves & Pitarka 2016). We generate three (X1, X2 and X3) 2-D random fields filtered using von Karman autocorrelation function. Then, from a linear combination of X1 and X2 (or X1 and X3) a new random variable X4 (or X5) is created. Finally, we generate three random fields Y1, Y2 and Y3 using X1, X4 and X5 which are properly scaled and have desired correlation among

them. The equations are as follows:

$$X4 = \rho\, X1 + \sqrt{1-\rho^2}\, X2 \ \text{ and } \ X5 = \rho\, X1 + \sqrt{1-\rho^2}X3, \quad (1)$$

where is the correlation coefficient, and

$$Y1 = \mu_1 + \sigma_1 X1; Y2 = \mu_2 + \sigma_2 X4; Y3 = \mu_3 + \sigma_3 X5, \quad (2)$$

where (μ_1, σ_1), (μ_2, σ_2) and (μ_3, σ_3) are mean and standard deviations of variables X1, X2 and X3, respectively. The new random variables Y1, Y2 and Y3 correspond to slip, rise time and rupture speed, respectively, having the desired correlation between Y1 and Y2 (nearly 0.6), and Y1 and Y3 (nearly 0.3).

We consider a 50 km long and 15 km wide strike-slip fault on which an earthquake occurs of seismic moment 2.8×10^{19} N m ($M_w = 6.9$). Fig. 1(a) shows spatial variations of slip, rise time and rupture speed on the fault plane. Note that the rupture parameters are cosine tapered (slip and rupture speed are decreased, whereas rise time is increased) towards the right edge of the fault to weaken the amplitude of stopping phase. In the case of earthquakes with supershear rupture speed, the rupture front initially propagates at a sub-Rayleigh velocity, but then transitions to supershear speed. Therefore, we assume that an unmodelled sub-Rayleigh rupture front arrives from some distance, and then transitions to supershear speed propagation on the modelled fault area (50 x 15 km). Correspondingly, rupture onset times on the modelled portion of the fault delineate an almost vertical rupture front (Fig. 1a). The location of minimum rupture onset time denotes the hypocentre (black star). Fig. 1(b) compares the CCDF of slip against three theoretical functions including log-normal, exponential and truncated exponential to examine the one point statistics. Our slip realizations are in proximity to truncated exponential behaviour. Figs 1(c–e) delineate the correlation among rupture parameters with a linear least-squares fit to the data. The strongest correlation exists between slip and rise time (nearly 60 per cent) compared to other pairs of rupture parameters. The temporal slip-rate evolution at each source point is described by the regularized Yoffe function (Tinti *et al*. 2005) with fixed acceleration time ($\tau_{acc} = 0.2$ s). We used constant τ_{acc} as the current observational constraints on it, though poor, indicate that τ_{acc} varies only weakly (Tinti *et al*. 2005). Strike and dip are $90°$, and the rake is uniformly set to $0°$ (left-lateral strike-slip).

We first generate five models having all the parameters heterogeneous (slip, rise time and rupture speed) denoted as MOD-I (I = 1, 2, 3, 4, 5). Fig. 1 shows MOD-1, the other four models are shown in Supplementary Information Fig. S1. We then create a set of 31 rupture models by combining heterogeneous and uniform rupture parameters (Table 1), in which the uniform values are chosen as the corresponding average slip (1.16 m), rise time (1.80 s) and rupture speed ($1.57V_s$). We refer to the models using their heterogeneous parameters, for example, MOD-1; H_{V_r} denotes the model created from MOD-1 with heterogeneous (H) rupture speed (V_r), but uniform slip and rise time. Similarly, MOD-2; H_{DT_r} indicates source generated using MOD-2 having heterogeneous slip (D) and rise time (T_r), but uniform rupture speed. We also define a reference rupture model with uniform parameters ($U_{DT_rV_r}$); thus, we consider in total 36 source models.

2.2 Receiver geometry and reference medium

Supershear ruptures propagating at constant rupture velocity V_r generate a planar shear Mach wave that is radiated off the fault at

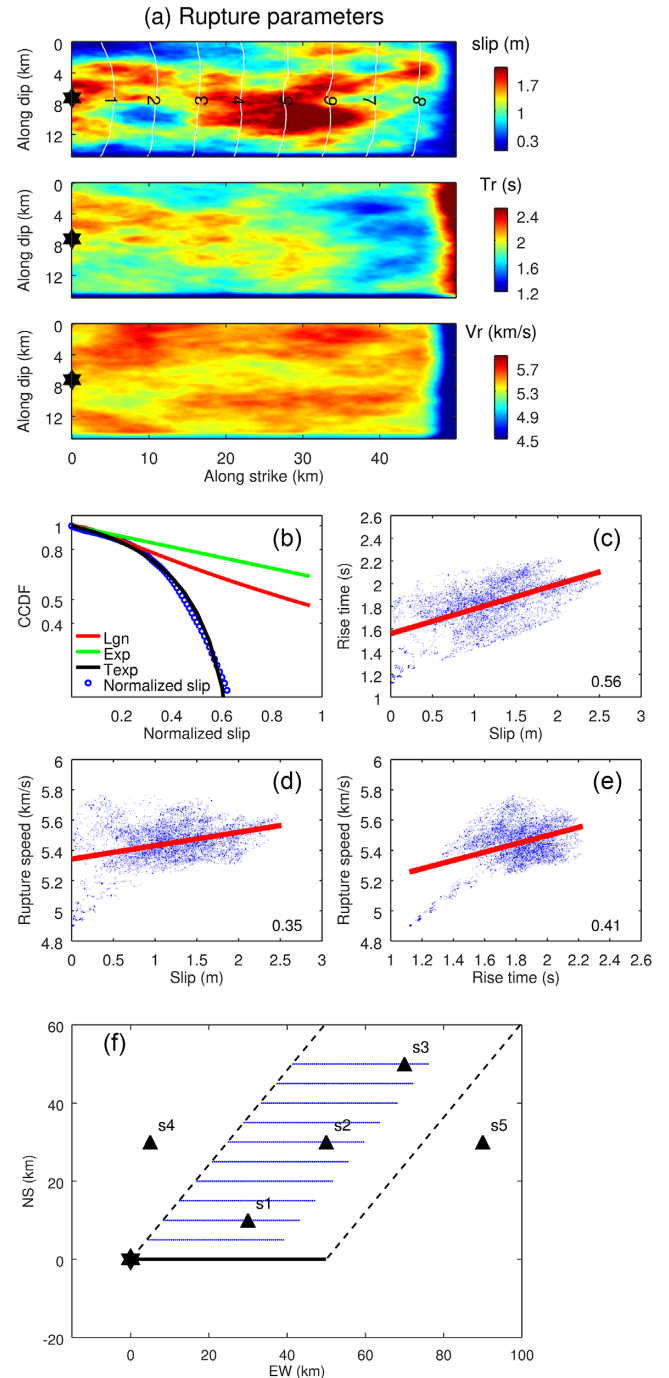

Figure 1. (a) Slip heterogeneities (white contours depict rupture time in seconds), rise time and supershear rupture speed variations (MOD-1) used for analysing effects on Mach wave coherence. The black star marks the hypocentre. (b) Complementary cumulative distribution function (CCDF) of the slip compared against log-normal (Lgn), exponential (Exp) and truncated exponential (Texp) distributions. Panels (c–e) depicts correlations among rupture parameters (correlation coefficient is given in the bottom right of the plots and red line shows the linear least-squares fit). (f) Receiver geometry for ground-motion analysis (blue dots) as well as waveform comparison (black triangles, s1 to s5). The black dashed lines show the theoretically estimated Mach boundaries for rupture speed $1.57V_s$. The solid black line depicts the fault trace, the black star marks the epicentre.

Table 1. 36 source models generated from combinations of uniform and heterogeneous rupture parameters using five different realizations (MOD-I, where I = 1, 2, 3, 4 and 5).

Model reference	D	T_r	V_r

an angle θ (e.g. Bizzarri *et al.* 2010):

$$\theta = \sin^{-1}\left(\frac{V_s}{V_r}\right). \tag{3}$$

Using eq. (3), we compute the spatial limits in which the Mach waves travel for average rupture speed (Fig. 1f; $V_r = 1.57V_s$). For our analysis, we examine simulated ground motions at lines of receivers within the theoretical Mach region boundaries (Fig. 1f), but ignore stations at the right end of these boundaries as they are affected by stopping phases. Receivers are spaced at 0.5 km in fault-parallel and 5 km in fault-normal directions. Five additional locations (s1–s5, Fig. 1f) are used to investigate waveform differences for receivers inside and outside the Mach boundaries.

2.3 Computation of synthetic seismograms

We use the Support Operator Rupture Dynamics code, which is a second-order accurate (in space and time) generalized finite-difference solver of the elastodynamic equations (Ely *et al.* 2008). The reference medium is a homogeneous half-space of uniform *S*-wave speed (3464 m s^{-1}), *P*-wave speed (6000 m s^{-1}) and density (2700 kg m^{-3}), to which random velocity and density perturbations are added for studying scattering effects (Section 4). The kinematic source is embedded as a point-cloud of local slip-rate functions over the designated rupture area. We use 12-points for the shortest wavelengths at a grid spacing of $dx = 50$ m, hence the maximum resolved frequency is 5 Hz (to remove unresolved frequencies from the analysis, the resulting seismograms are low-pass filtered using a fourth-order Butterworth filter). The corresponding computational time step ($dt = 0.0045$ s) is set to satisfy the numerical stability criteria (e.g. Ely *et al.* 2008).

3 EFFECTS OF HETEROGENEOUS SOURCE PARAMETERS

We investigate simulated ground motions with Mach front signatures for the heterogeneous source models, and compare those to waveforms for the uniform reference source. These 36 simulations are run using the homogeneous medium and identical receiver geometry to focus on source effects only.

3.1 Synthetic seismograms and wavefield snapshots

Fig. 2 compares fault-parallel (FP), fault-normal (FN) and vertical (Ver) components of ground acceleration for source MOD-1 and the reference source $U_{DT_rV_r}$ at stations s1–s5 (Fig. 1f; recall that s1, s2 and s3 are within the Mach boundary, s4 and s5 are outside). Sites s3 and s2 clearly show the *S*-Mach wave and Rayleigh–Mach wave,

while at site s1 there is no clear separation between the two. The Rayleigh–Mach wave is most strongly developed on the vertical component, while the *S*-Mach wave is only expressed on the horizontal components. The overall horizontal component Mach wave amplitudes from MOD-1 are smaller than $U_{DT_rV_r}$, especially close to the fault (sites s1 and s2), illustrating the effects of rupture parameter heterogeneities. For both sources, site s4 shows significantly lower ground acceleration than site s3 (∼8 times on the fault-normal and ∼25 times on the vertical component), although s4 is closer to the fault than s3. Site s5 is located in the direction of rupture propagation, and hence experiences a strong stopping phase arrival before the *S*-wave, whereas s4 does not (because it is located in the opposite direction). The ground-velocity amplitudes for sources MOD-1 and $U_{DT_rV_r}$ at these two sites show similar characteristics (Supplementary Information Fig. S2), indicating larger ground motions for locations inside the Mach boundaries than outside.

Fig. 3 displays snapshots of ground acceleration for source models $U_{DT_rV_r}$ and MOD-1, illustrating the planar Mach waves due to supershear rupture propagation and a strong stopping phase from sudden rupture arrest at the right fault edge (nicely seen on fault-parallel at 12 s and beyond). The fault-parallel and fault-normal components both show the *S*-Mach wave and Rayleigh–Mach wave, while the vertical component only contains the Rayleigh–Mach wave. Mach wave amplitudes almost remain unchanged as the waves propagate, even at larger distance from the fault due to their planar nature (perfect planar in 2-D and more complex in 3-D). The wavefield of ground velocity exhibits similar Mach wave characteristics as the acceleration wavefield (Supplementary Information Fig. S3); for both sources, Mach waves travel large distances without significant attenuation. However, Mach wave velocity/acceleration amplitudes are smaller for model MOD-1 than for the reference source $U_{DT_rV_r}$.

3.2 Peak ground acceleration

To further quantify ground-motion characteristics due to the effects of source complexity on Mach wave coherence, we calculate peak ground acceleration (PGA) of the two horizontal components using GMRotD50 method (Boore *et al.* 2006; calculated by stepwise rotating the two orthogonal horizontal components by 1° increments from 1°–90°, computing the geometric mean for each pair, and taking PGA as the median of 90 geometric means).

We examine mean and standard deviation of PGA computed using all stations for a given fault-perpendicular distance for the 36 models. Fig. 4(a) compares PGA values for six source models (five sources having D, T_r and V_r heterogeneous; and reference source) as function of distance, showing also the PGA estimates using the ground motion prediction equation (GMPE) of Boore and Atkinson (2008; henceforth BA2008). The mean PGA values computed using six sources fall outside the one-sigma bounds of BA2008 at distances of 10 km and beyond. However, at a distance of 5 km the PGA estimates from the GMPE and our simulations are comparable. At this distance, rupture parameter heterogeneity seems to exert strong effects on ground shaking (note the variations of mean PGA, for MOD-1 being lowest to MOD-2 being highest). The overprediction of the simulated PGA values at larger distances is likely due to the omission of scattering in these simulations. The mean PGA for $U_{DT_rV_r}$ remains almost constant with distance, because the planar Mach wave has negligible attenuation over the modelled distances. Fig. 4(b) compares PGA values for five source models with only heterogeneous rise time to the reference source and BA2008. The rupture models with only T_r heterogeneous are
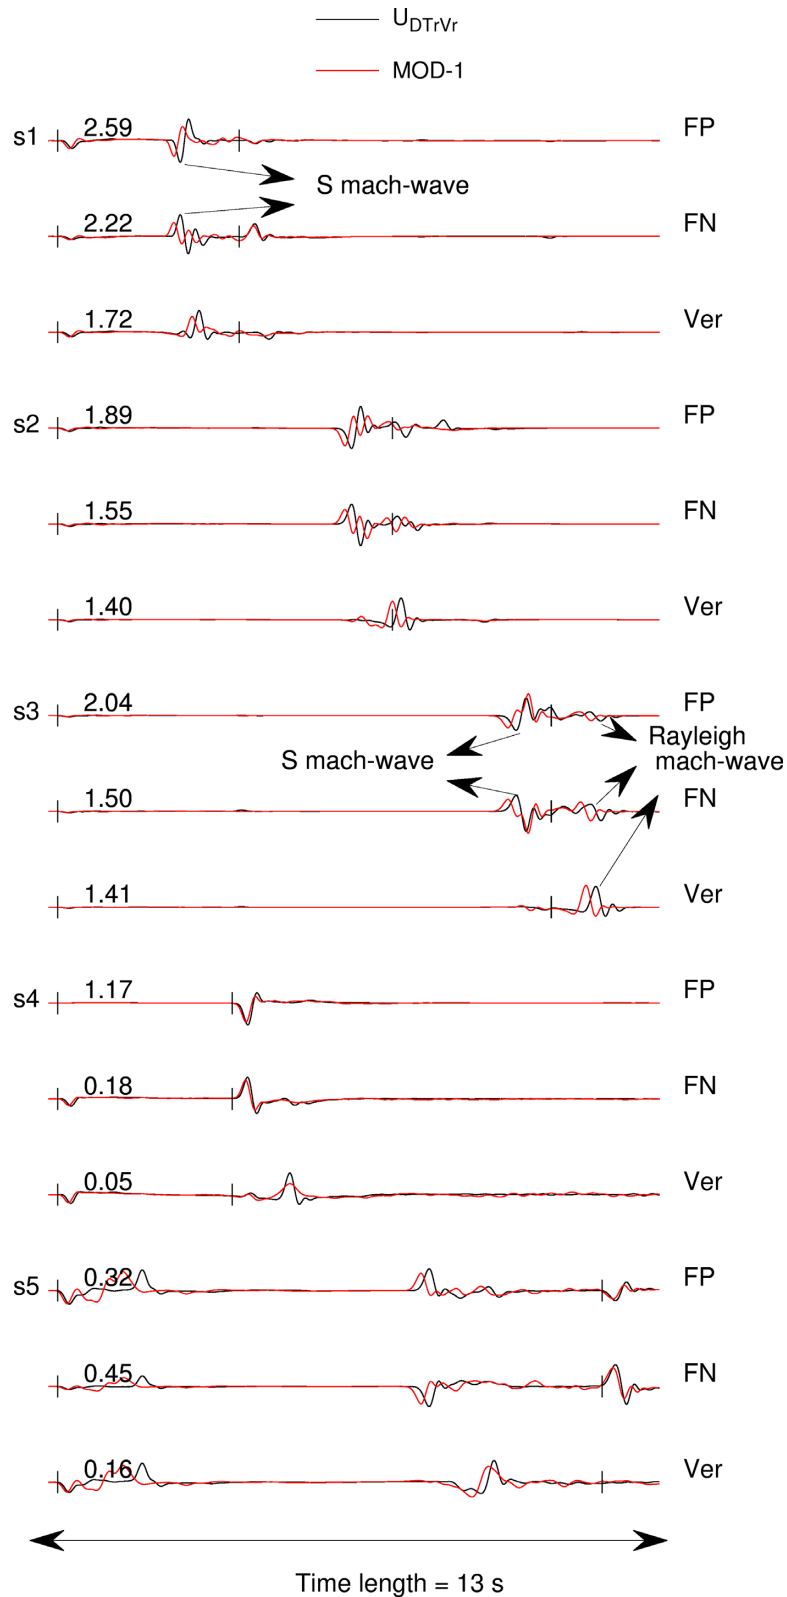

Figure 2. Ground acceleration (m s^{-2}) for fault-parallel (FP), fault-normal (FN) and vertical (Ver) components, comparing MOD-1 to the reference source $U_{DT_rV_r}$ at five stations (s1–s5, Fig. 1f). Theoretical arrivals from the epicentre of *P* and *S* waves (black bars) are also shown. Waveforms are aligned according to the theoretical *P*-wave arrival and normalized with respect to the absolute maximum of the two sources for a given component (indicated in upper left corner). The *S*-Mach wave and Rayleigh–Mach wave are also marked.
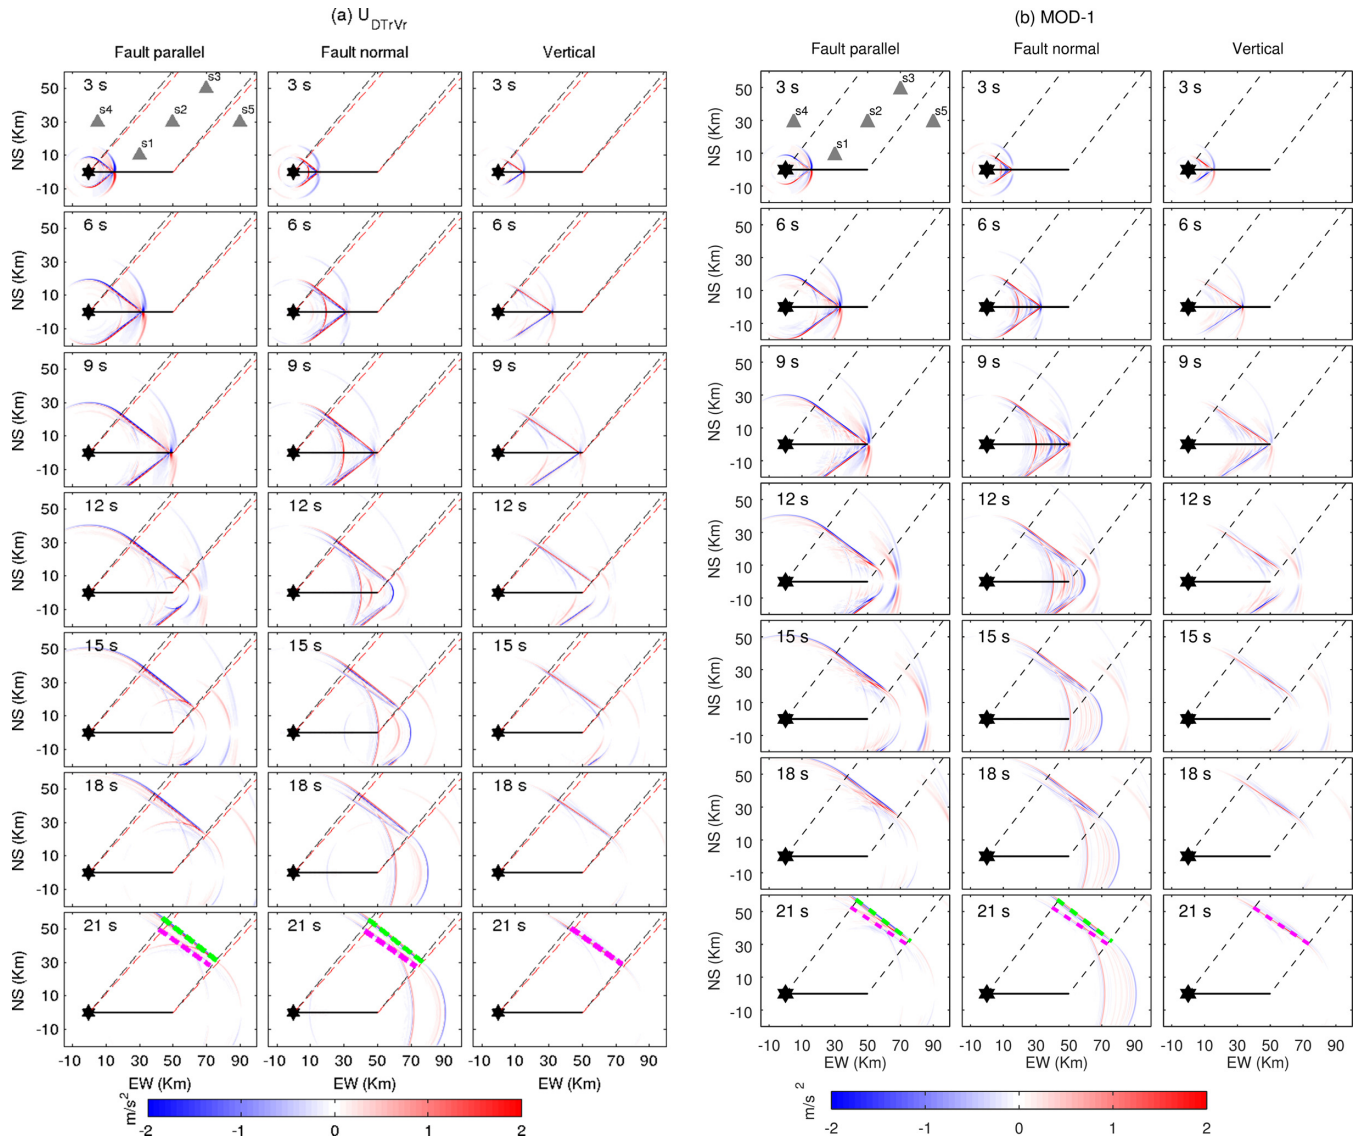

Figure 3. Snapshots of the ground-acceleration wavefield, for the three components of motion computed using the reference source $U_{DT_rV_r}$ and MOD-1. The S-Mach wave (green dashed line) and Rayleigh–Mach wave (magenta dashed line) are marked to show their planar nature and orientation with respect to the fault. The Mach waves travel large distances from the fault without any attenuation.

comparable/lower (but not higher) than reference source. The PGA comparisons for source models having heterogeneities only in D, or V_r, or (D, T_r), or (D, V_r) or (T_r, V_r) are shown in Supplementary Information Fig. S4.

To further summarize the results, we compute mean and standard deviation of PGAs from five realizations sharing the same rupture parameter heterogeneity and using all stations for a given fault-perpendicular distance. For example, we use PGAs from the five realizations MOD-1, 2, 3, 4 and 5; H_{T_r} (five different curves in Fig. 4b) and all receivers at a given distance to obtain the average estimate (a single representative mean curve of those five curves) denoted as $(H_{T_r})_{avg}$. We use abbreviations $(H_D)_{avg}$, $(H_{T_r})_{avg}$, $(H_{V_r})_{avg}$, $(H_{DT_r})_{avg}$, $(H_{DV_r})_{avg}$, $(H_{T_rV_r})_{avg}$ and $(H_{DT_rV_r})_{avg}$ to refer to the averages over five realizations considering heterogeneities only in D, or T_r, or V_r, or (D, T_r), or (D, V_r) or (T_r, V_r) or (D, T_r, V_r), respectively. Figs 4(c and d) compare PGA estimates calculated by averaging over five realizations for a given kind of heterogeneity to the reference source and BA2008. The PGAs from $(H_D)_{avg}$, $(H_{T_r})_{avg}$ and

$(H_{DT_r})_{avg}$ are comparable/lower (but not higher) than the $U_{DT_rV_r}$ for all distances, with $(H_{DT_r})_{avg}$ being the lowest indicates that both slip and rise time heterogeneities slightly reduce the Mach wave coherence. The physical explanation could be that the peak slip velocity (PSV) dominantly controls the peak ground motion, and PSV is mainly controlled by slip and rise time for fixed acceleration time. In general, we observe that the source rise time and slip heterogeneities slightly lower the PGA values from supershear ruptures in near-fault distances ($\leq$10 km).

3.3 Average Fourier acceleration

To investigate the spectral characteristics of the seismic wavefield, we calculate Fourier spectra of unfiltered acceleration time-series at each site. We then compute the average Fourier acceleration (AFA) as the mean of the spectra for multiple sites at a given distance from the fault. Fig. 5 compares AFA for the fault-parallel and fault-normal components for the six sources. The variations in AFAs for MOD-1,
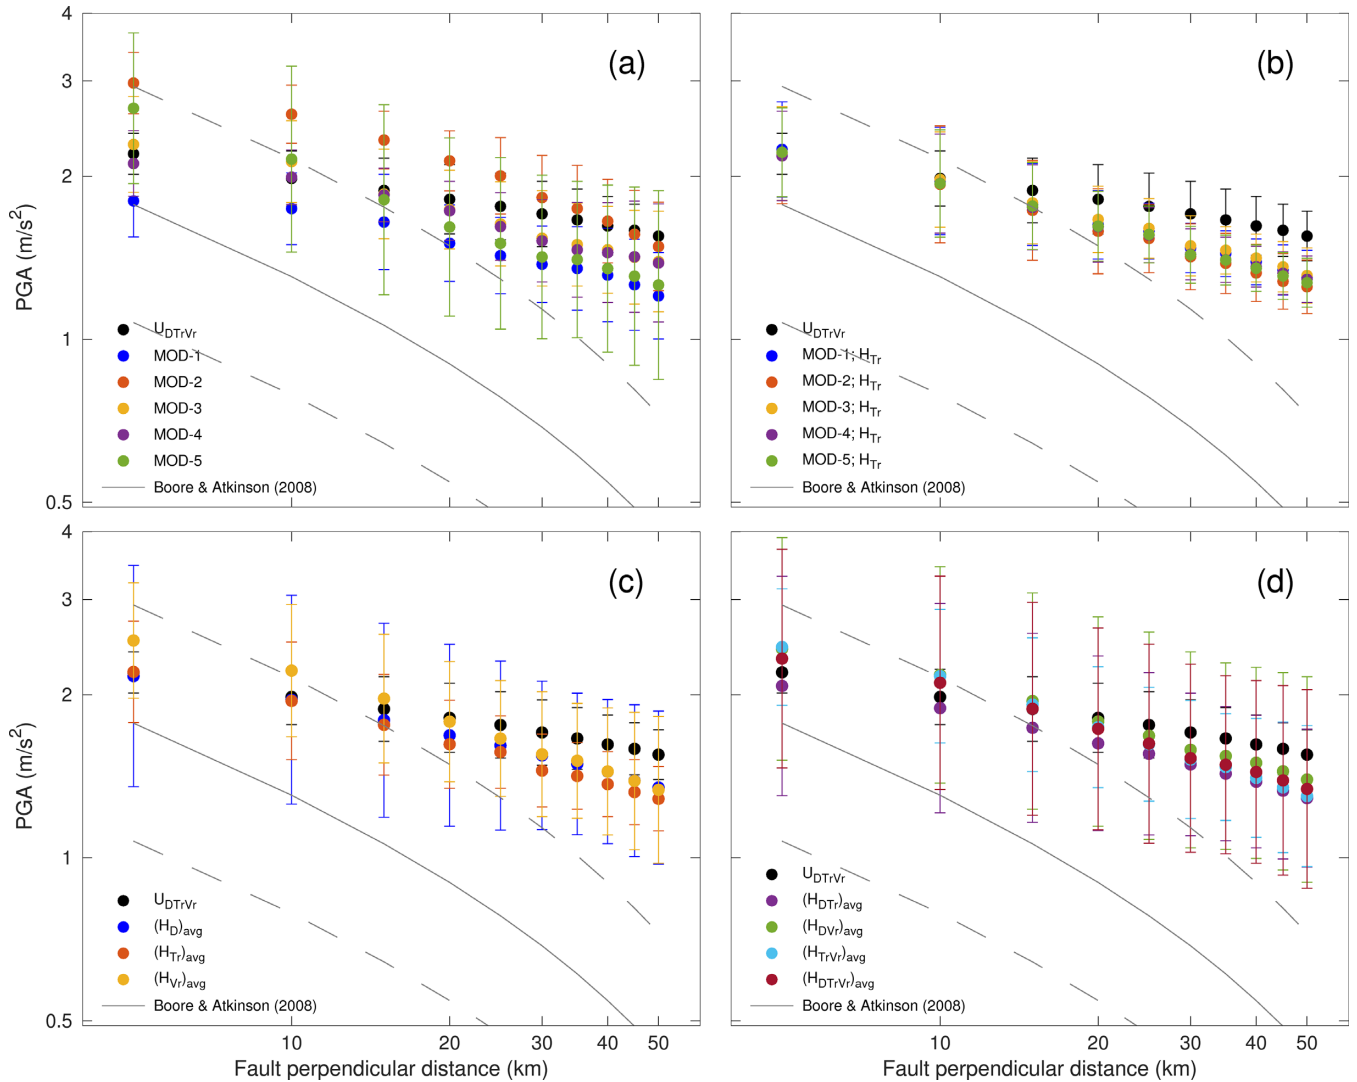

Figure 4. (a and b) PGA as a function of distance for 11 rupture models depicts the effects of rupture heterogeneity on ground motions generated from supershear ruptures. The mean (circles) and standard deviation (bars) of PGA are computed using stations at a given fault-perpendicular distance. The median (solid line) and one-sigma bounds (dashed lines) of PGA from BA2008 are shown for comparison. Note the variations of mean PGA for sources having heterogeneities in D, T_r and V_r (left-top plot) with respect to $U_{DT_rV_r}$. The rupture models having heterogeneities only in rise time (right-top plot) lead to equal/lower mean PGA compared to reference source. (c and d) PGA averaged over five realizations for a given heterogeneity (so, five PGA curves in Fig. 4(a) corresponding to MOD-1, 2, 3, 4 and 5 are represented by one curve in Fig. 4(d) as $(H_{DT_rV_r})_{avg}$) as function of distance showing overall effects of rupture parameters heterogeneities on Mach wave coherence.

2, 3, 4 and 5 compared to $U_{DT_rV_r}$ at 5 km distance depict the effects of rupture parameter heterogeneity on frequency content of ground motions generated from supershear ruptures. At larger distances (≥ 20 km), the variations among the AFAs are lower compared to a distance of 5 km. The AFAs for sources having heterogeneity only in rise time show less fluctuations compared to rupture models having heterogeneity in all parameters (compare Fig. 5 with Supplementary Information Fig. S5).

4 EFFECTS OF SCATTERING MEDIUM

We now investigate the effects of seismic scattering on Mach wave characteristics by computing the seismic wavefield for $U_{DT_rV_r}$ embedded into realizations of heterogeneous 3-D earth media. The resulting ground motions are analysed analogous to the homogeneous-medium case.

4.1 Realization of 3-D random media

Small-scale heterogeneities in Earth structure cause seismic scattering that leads to wave front distortion, redistribution of wave energy and pronounced changes of seismic waveforms. Frankel & Clayton (1986) studied scattering of elastic and acoustic waves in 2-D random media characterized by variations in seismic wave speeds. They considered three different correlation functions (Gaussian, exponential and self-similar von Karman), and observed that 2-D self-similar random media with 5 per cent velocity fluctuations and correlation lengths of 10 km (or greater) may explain traveltime anomalies across seismic arrays and the coda waves of microearthquakes. Ritter et al. (1998) analysed teleseismic P-wave recordings to determine scattering-media parameters of the lithosphere. For their study region (central France), they proposed a model of the lithosphere consisting of a heterogeneous layer of 70 km thickness with correlations lengths of 1–16 km and velocity
Figure 5. Average Fourier amplitude (AFA) spectra as a function of frequency for the fault-parallel (FP) and fault-normal (FN) components of ground motion for six source models at different fault-perpendicular distances (5, 20, 35 and 50 km). Note the variations of AFA for different rupture models compared to reference source.

fluctuations of 3–7 per cent. These values are in agreement with Rothert & Ritter (2000) who determine the small-scale heterogeneous structure of the upper lithosphere beneath the Grafenberg array, Germany, and find wave speed perturbations of 3–7 per cent and correlation lengths of 0.6–4.8 km.

We introduce small-scale heterogeneities into a homogeneous background model by adding a spatial random field, characterized by an isotropic von Karman autocorrelation function, following the approach of Imperatori & Mai (2013). The power spectral density of the von Karman function is described as

$$p(k) = \frac{\sigma^2 \left(2\sqrt{\pi}a\right)^3 \Gamma(H+1.5)}{\Gamma(H)\left(1 + k^2 a^2\right)^{(H+1.5)}}, \qquad (4)$$

where a, H, σ, k and are correlation length, Hurst exponent, standard deviation, wavenumber and the Gamma function, respectively. We generate six realizations of the 3-D random field using three correlation lengths (5.0, 2.0 and 0.5 km) and two standard deviations (5 and 10 per cent) for fixed Hurst exponent ($H = 0.2$). The choice of these parameters values is motivated by data analysis using borehole logs and seismic reflection data (e.g. Dolan & Bean 1997; Bean *et al.* 1999). The six realizations of randomized 3-D

Table 2. Six 3-D earth models generated from combinations of correlation lengths and standard deviations with fixed Hurst exponent.

| Model reference	Correlation length a (km)	Standard deviation σ (per cent)	Hurst exponent H
M1	5.0	5	0.2
M2	2.0	5	0.2
M3	0.5	5	0.2
M4	5.0	10	0.2
M5	2.0	10	0.2
M6	0.5	10	0.2

Figure 6. Surface slices of shear wave speed for the six realizations of 3-D random earth models, using combinations of three correlation lengths (5.0, 2.0 and 0.5 km) and two standard deviations (5 and 10 per cent) for fixed Hurst exponent ($H = 0.2$). The solid black line depicts the fault trace; the black star marks the epicentre.

earth models (having variations in velocity as well as density) are referred to as M1–M6 (Table 2), shown in terms of surface slices of *S*-wave speed to illustrate the effects of different correlation lengths and standard deviations (Fig. 6).

We place the reference source $U_{DT_r V_r}$ in six different random media, and conduct ground-motion simulations for the same receiver geometry as before. Due to regions of lower shear wave speeds in these random-media realizations, we have to reduce the spatial grid size to $dx = 25$ m and the computational time steps to $dt = 0.0018$ and 0.0014 s for media with standard deviations of 5 and 10 per cent, respectively.
Figure 7. Ground acceleration (m s^{-2}) for the fault-parallel (FP), fault-normal (FN) and Vertical (Ver) components, comparing two heterogeneous media M1 and M4 with the homogeneous medium at five stations (s1–s5, Fig. 1f). Theoretical *P*- and *S*-wave arrival times (for the homogeneous medium) are shown for reference. Waveforms are aligned according to the theoretical *P*-wave arrival time, and are normalized with respect to absolute maximum of motion within the three media for a given component (indicated in upper left corner).
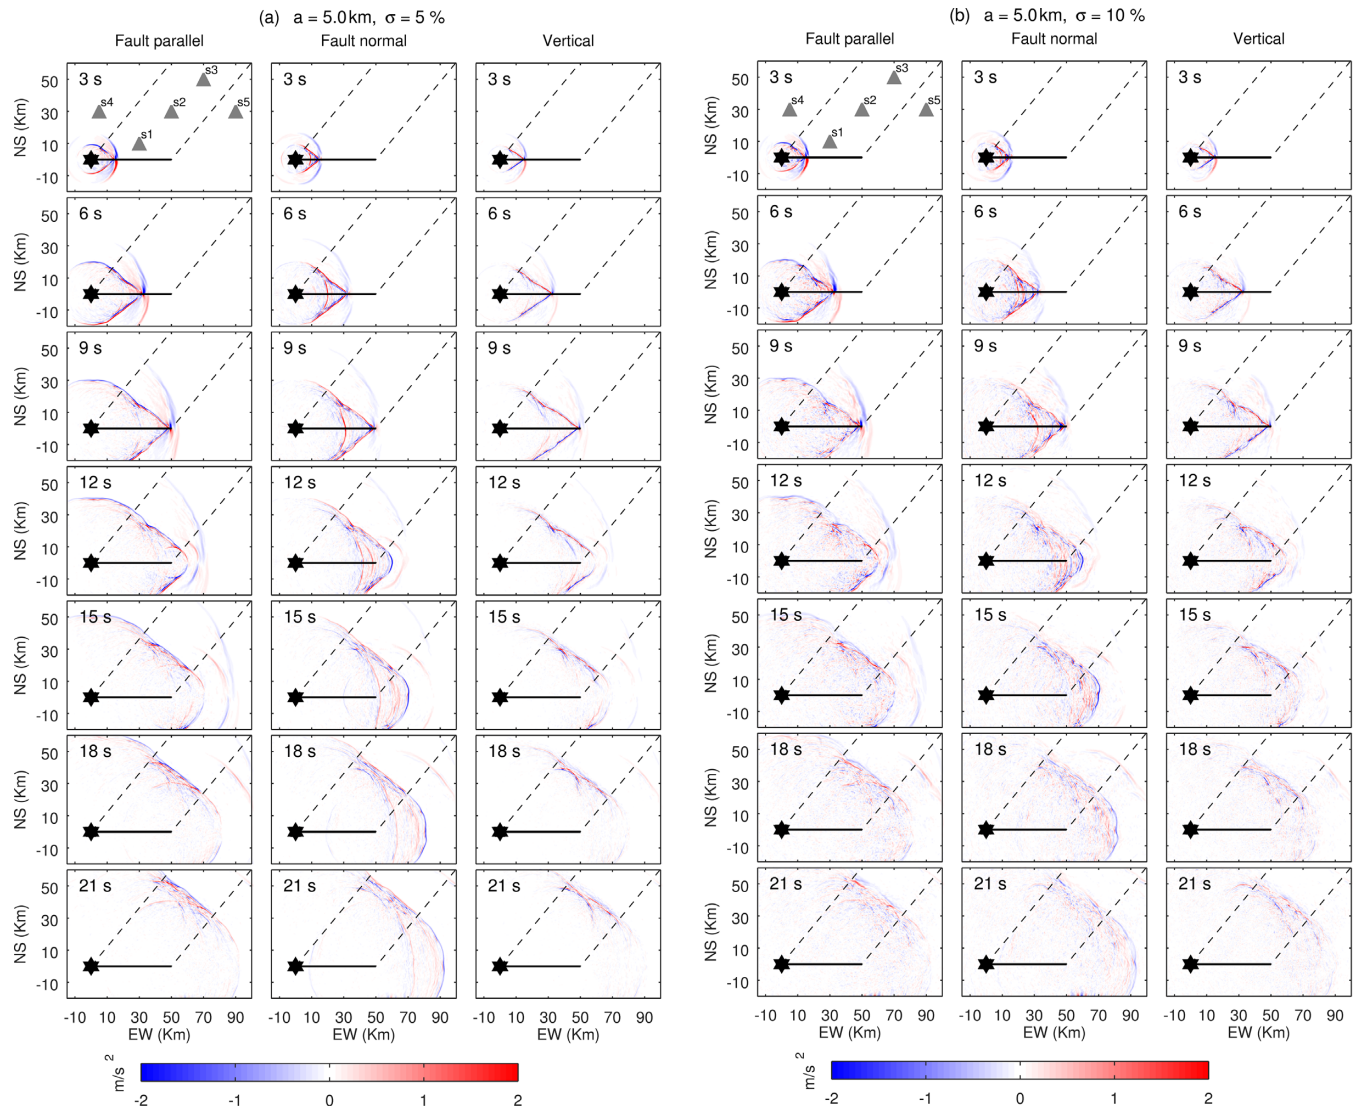

Figure 8. Snapshots in time of the acceleration wavefield at the Earth's surface for three components (FP, FN and Ver) for media M1 ($a = 5.0$ km, $\sigma = 5$ per cent) and M4 ($a = 5.0$ km, $\sigma = 10$ per cent). As the Mach wave travels away from the fault, peak amplitudes decrease due to seismic scattering. Scattering effects, and hence amplitude reductions, are larger for medium with $\sigma = 10$ per cent.

4.2 Synthetic seismograms and wavefield snapshots

Fig. 7 compares fault-parallel, fault-normal and vertical components of ground acceleration at sites s1–s5 (Fig. 1f) for M1 ($a = 5.0$ km, $\sigma = 5$ per cent) and M4 ($a = 5.0$ km, $\sigma = 10$ per cent) with the homogeneous-medium case, using the uniform source model. *S*-wave Mach amplitudes at station s1 on the fault-parallel and fault-normal components are smaller for M4 than for the homogeneous medium. As the *S*-Mach waves propagate away from the fault, amplitudes are further reduced for M4 compared to the homogeneous medium due to the cumulative effects of seismic scattering. The *S*-Mach wave amplitudes at sites s2 and s3 for M4 are comparable to scattered-wavefield amplitudes arriving after the *S*-Mach wave, suggesting that medium scattering may potentially obfuscate Mach wave detection in real earthquakes. Scattering of the *S*-Mach waves is stronger for M4 than for M1, due to the higher standard deviation of the random wave speed fluctuations. Sites outside the Mach boundaries (s4 and s5) also experience larger scattering for M4 than M1. Rayleigh–Mach waves on the vertical components of s1 and s2 have comparable amplitudes for all three

media, but have smaller amplitude at site s3 for media M4 and M1 compared to the homogeneous medium. Ground-motion velocities at the five stations s1–s5 for media M1 and M4 exhibit generally similar scattering effects as seen in ground acceleration (Supplementary Information Fig. S6). In general, Mach wave amplitudes are reduced in media with small-scale random heterogeneities (especially for $\sigma = 10$ per cent), compared to the homogeneous medium, since the elastic scattering redistributes the wave energy in space and time.

Fig. 8 shows snapshots of ground-motion acceleration at different times for media M1 ($a = 5.0$ km, $\sigma = 5$ per cent) and M4 ($a = 5.0$ km, $\sigma = 10$ per cent). The corresponding snapshots of ground velocity are provided in Supplementary Information Fig. S7, but seismic scattering is more prominently visible in the acceleration wavefield. As the Mach wave travels away from the fault, its amplitude decreases and its coherence is reduced. In fact, the scattering effects are so strong for M4 that the plane-wave structure of the Mach wave is difficult to identify after 9 s. In addition, the
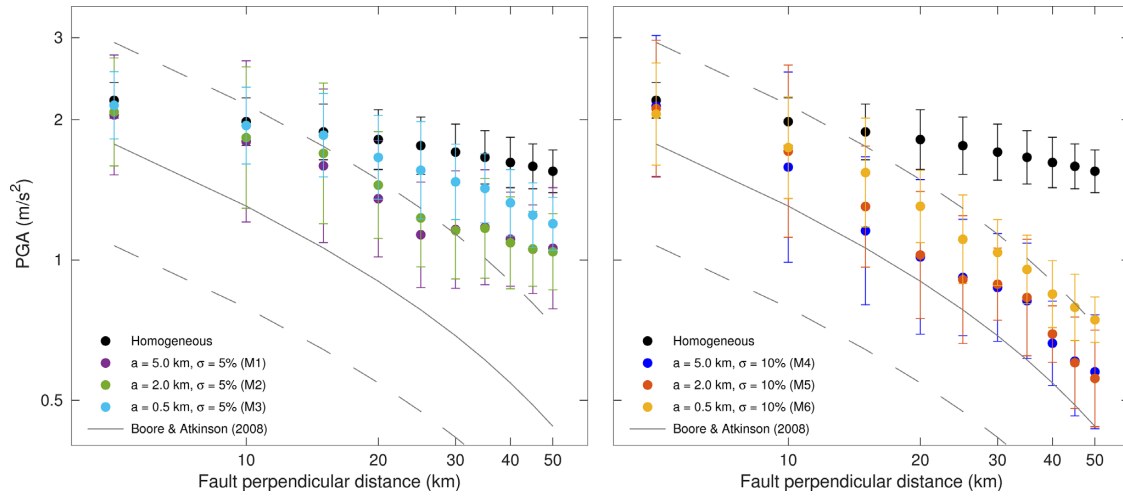

Figure 9. PGA as function of distance for six heterogeneous media and the homogeneous medium depicts the effects of seismic scattering on ground-shaking levels from supershear ruptures. The mean (circles) and standard deviation (bars) of PGA are computed using stations at given fault perpendicular distance; median (solid line) and one-sigma bounds (dashed lines) of PGA estimates from BA2008 are plotted for comparison. Note how small-scale media heterogeneities lower the mean PGA, especially for M4 and M5 (blue and orange dots).

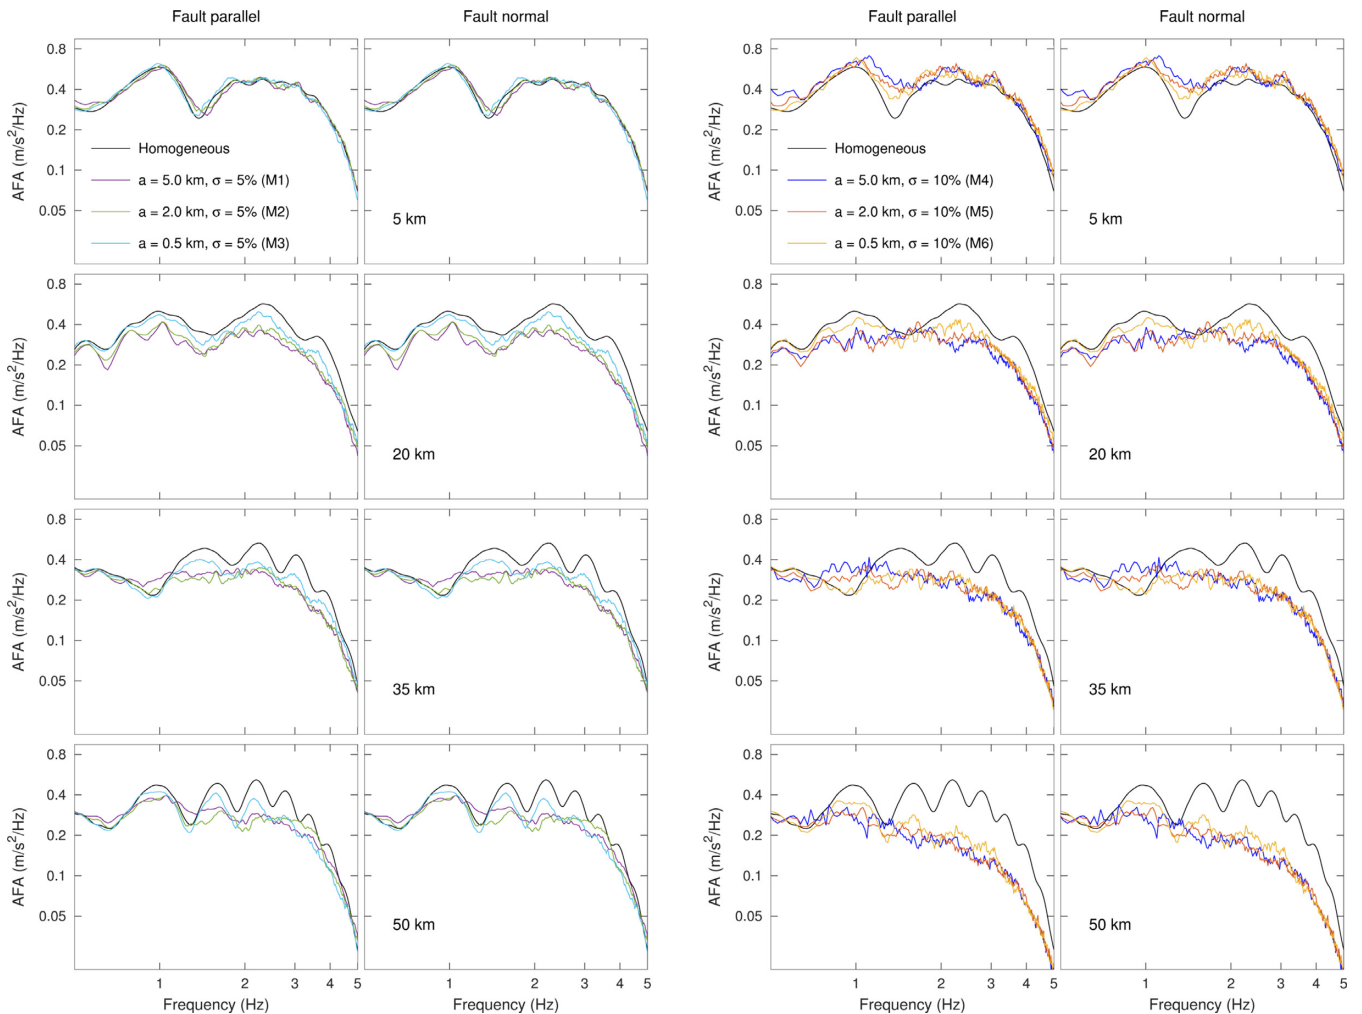

Figure 10. Average Fourier amplitudes (AFA) as a function of frequency for fault-parallel (FP) and fault-normal (FN) components of ground motion for the six heterogeneous media and homogeneous medium at different fault perpendicular distances (5, 20, 35 and 50 km). The AFA decreases with increasing distance from the fault. But we note that, the AFA decline with distance for M4, M5 and M6 is considerably larger than for M1, M2 and M3.

amplitudes of the scattered wavefield and the Mach wave become comparable (as seen already on seismograms s1–s3).

4.3 Peak ground acceleration

Following our previous approach, we quantify the effects of seismic scattering in heterogeneous media using PGA values as a ground-motion intensity measure. Fig. 9 displays PGA values for the six scattering media M1–M6 and the homogeneous medium for simulations with the uniform source model; PGA computed using BA2008 facilitates the comparison. The mismatch between GMPE estimates and simulations can partially be attributed to the absence of rupture complexity in these simulations. Mean PGA values for M1 and M2 ($\sigma = 5$ per cent) are near or just outside the one-sigma bound of BA2008 for all distances, while mean PGA for M4 and M5 ($\sigma = 10$ per cent) are within the one-sigma bound of BA2008. For distances larger than ~10 km, mean PGA values from BA2008 and our simulations begin to converge. The standard deviation of medium heterogeneities seems to control the seismic scattering rather than correlation length for small H (≤ 0.2). The wavefield scattering for medium M3 is smaller than M1 and M2 as the correlation length of 0.5 km is smaller than the minimum physical wavelength corresponding to background homogeneous medium ($3.464/5 \sim 0.7$ km). Due to the same reason, M6 shows lower Mach wave scattering compared to M4 and M5. In summary, we find that seismic scattering due to small-scale random heterogeneities in the Earth destroys the coherence of Mach waves, and thus complicates their observation in nature.

4.4 Average Fourier acceleration

We examine the spectral characteristic of scattered Mach waves by comparing AFA spectra computed as mean amplitude spectra for stations at a given distance from the fault. Fig. 10 depicts AFA spectra as a function of frequency for the horizontal components of motion for the homogeneous and six heterogeneous media. All AFA spectra are similar, on both components, at 5 km distance, showing that scattering is relatively unimportant at these close distances. With increasing distance, AFA spectra for scattering media decrease more rapidly than for the homogeneous medium, at all frequencies above 1 Hz, due to the cumulative nature of scattering effects. We also observe that AFA spectra for M4, M5 and M6 ($\sigma = 10$ per cent) decrease more rapidly than for M1, M2 and M3 ($\sigma = 5$ per cent), indicating that seismic scattering is controlled by the standard deviation of the velocity fluctuations.

5 EFFECTS OF COMBINED SOURCE AND MEDIUM HETEROGENEITIES

Mach wave coherence is affected by slip and rise time heterogeneities at close fault distances (<10 km), whereas the influence of seismic scattering becomes dominant beyond larger distances (>10 km). However, in nature all rupture parameters are most likely heterogeneous (D, T_r and V_r), therefore, we choose MOD-1 and MOD-2 (also end-members in terms of mean PGA at 5 km distance, see Fig. 4a) as representative heterogeneous rupture models. We select random medium M4 as an end-member medium due to its strongest impact on Mach waves (see Section 4). Now, we combine both source and medium heterogeneities to examine their overall effects on the Mach wave. We then analyse the synthetic ground motions at several receivers like in Sections 3 and 4.

5.1 Synthetic seismograms and wavefield snapshots

Fig. 11 compares fault-parallel, fault-normal and vertical components of ground acceleration from MOD-1 in M4 to $U_{DT_rV_r}$ in a homogeneous medium at locations s1–s5. The S-Mach wave amplitudes on fault-parallel and fault-normal at s1 are now even smaller, because of the combined source and medium heterogeneities, compared to considering each case individually (compare Fig. 11 with Figs 2 and 7). The Rayleigh–Mach wave amplitudes on the vertical component are lower for MOD-1 in M4 than in the reference case at station s3, but are comparable at sites s1 and s2. Therefore, they are mostly affected by medium heterogeneities, while the source heterogeneities have smaller effects. The particle velocities are also lower at stations s1 and s3 for MOD-1 in M4 than in the reference case, whereas comparable at s2 (Supplementary Information Fig. S8).

The fault-parallel, fault-normal and vertical components of ground acceleration (Fig. 12) and ground velocity (Supplementary Information Fig. S9) are displayed for MOD-1 in M4. The scattering effects are more prominent in the acceleration wavefield compared to velocity wavefield. Nevertheless, the planar structure of the Mach pulse is harder to recognize in acceleration/velocity snapshots at 9 s and beyond.

5.2 Peak ground acceleration

We apply the same approach as before and compute PGA to examine the effects of combined source and medium heterogeneities. Fig. 13 compares PGA values from MOD-1 and MOD-2 in M4 to $U_{DT_rV_r}$ in the homogeneous medium. The PGA from BA2008 are plotted to facilitate comparisons. The mean PGA values from MOD-1 and MOD-2 in M4 are comparable to BA2008 (MOD-1 in M4 being closer), whereas those from $U_{DT_rV_r}$ in the homogeneous medium remain significantly higher. The physical explanation is the presence of source effects in the near field (<10 km), while medium scattering effects are dominant only at larger distances (>10 km), leading to overall diminished Mach wave amplitude at all distances. Additionally, the PGA at stations s4 and s5 (which are outside the theoretical Mach cone boundary) for MOD-1 in M4 are within the one-sigma bounds of BA2008, indicating that our choices for source and medium parametrizations are reasonable. Moreover, we check the effects of intrinsic attenuation on PGA levels from MOD-1 in M4. We apply Futterman filter (e.g. Varela *et al.* 1993) which depends on Q and traveltime as post-processing to the synthetic waveforms. We adopt a constant Q value of 350 ($\sim V_s/10$) following Chandler *et al.* (2006). We observe negligible reduction in PGA (~ 0.2 per cent) due to intrinsic attenuation for MOD-1 in M4, and therefore, it is not shown in Fig. 13.

Overall, we find that for scenarios with combined source and medium heterogeneities, the Mach wave coherence is strongly reduced, which in turn leads to the effect that PGA levels are not elevated when compared to a GMPE. Therefore, source and medium complexity destroy the theoretically expected stronger shaking for supershear ruptures.

5.3 Average Fourier acceleration

Fig. 14 illustrates the AFA for fault-parallel and fault-normal components of ground acceleration for MOD-1 and 2 in M4 and $U_{DT_rV_r}$ in the homogeneous medium. The AFA for MOD-1 in random medium M4 is close to $U_{DT_rV_r}$ in homogeneous medium at 5 km distance. The source effects are masked by medium scattering already at
Figure 11. Ground acceleration (m s^{-2}) for the fault-parallel (FP), fault-normal (FN) and Vertical (Ver) components, comparing MOD-1 in M4 to $U_{DT_rV_r}$ in the homogeneous medium at five stations (s1–s5, Fig. 1f). The theoretical *P*- and *S*-wave arrival times in the homogeneous medium are shown for reference. Waveforms are aligned according to the epicentral *P*-arrival time and normalized with respect to absolute maximum of two signals for a given component (indicated in the upper left corner).
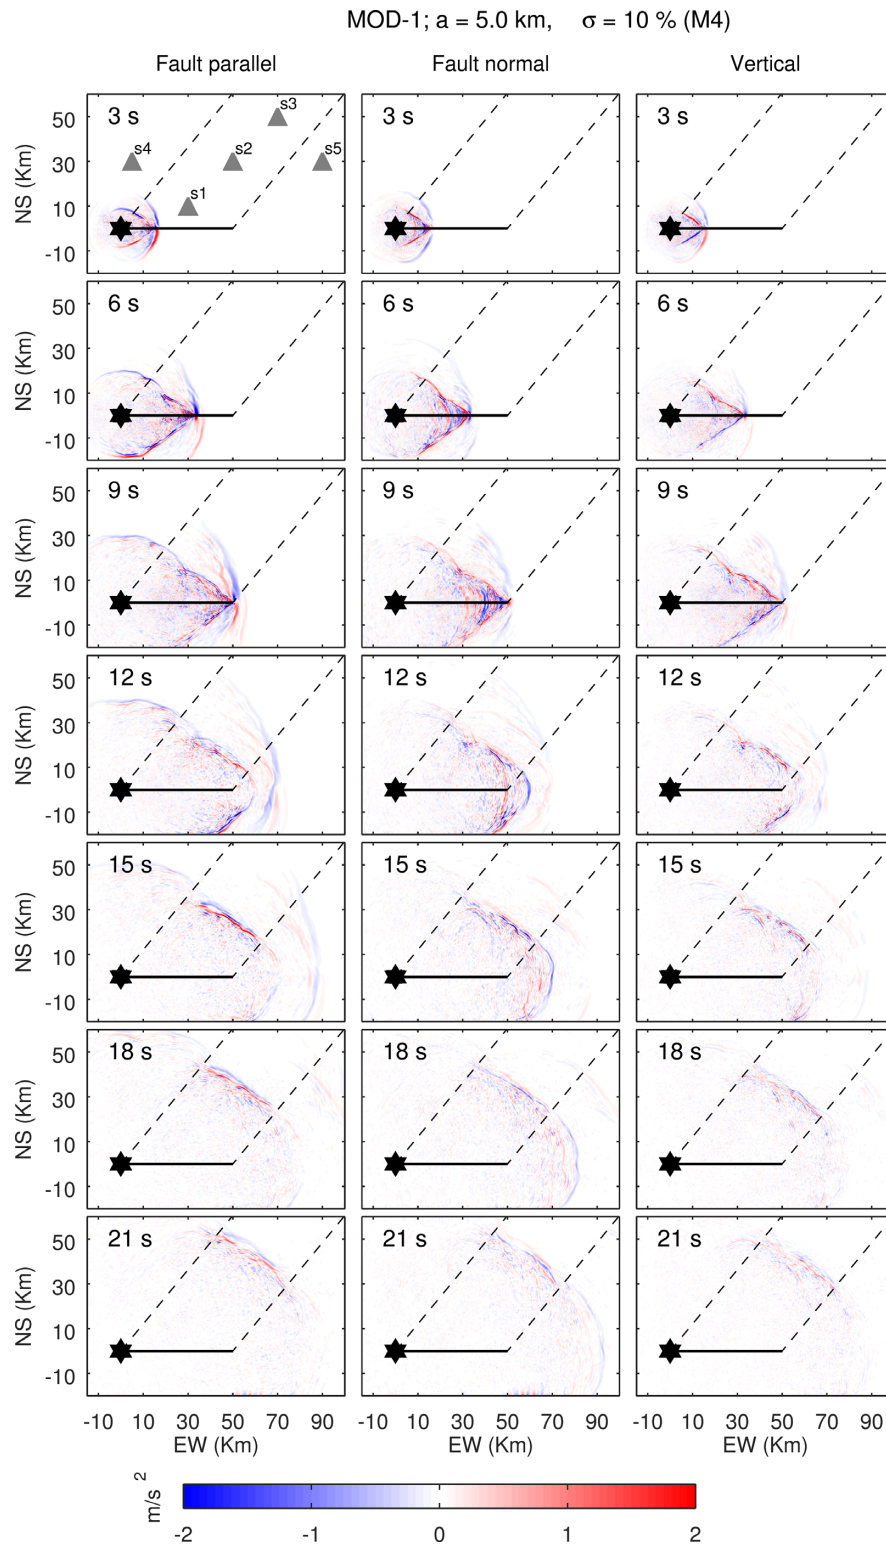

Figure 12. Snapshots in time of the acceleration wavefield at the Earth's surface for the three components for source model MOD-1 in M4. Rupture parameters heterogeneities of MOD-1 lower the Mach wave amplitudes, which are then further reduced by scattering as the Mach wave travels away from the fault.

5 km distance; otherwise, lower AFA is expected for MOD-1 in the homogeneous medium (see Fig. 5). The AFA for MOD-2 in M4 is higher than $U_{DT_r V_r}$ at 5 km distance due to the dominance of source effects as previously observed for MOD-2 in homogeneous medium (see Fig. 5). The AFA decreases with increasing distance

for MOD-1 and 2 in M4 faster than the reference case beyond 1 Hz, but the decline from combined source and medium heterogeneities is comparable to what is seen in the case of medium heterogeneities only (compare Fig. 14 with Fig. 10). At 35 km (and beyond), the AFA from MOD-2 in M4 approaches MOD-1 in M4. Overall, we
Figure 13. PGA as a function of distance for sources MOD–1 and 2 in M4, and $U_{DT_rV_r}$ in the homogeneous medium. The comparisons show the effects of combined source and medium heterogeneities on ground-motion levels. The median (solid line) and one-sigma bounds (dashed lines) of PGA estimates from BA2008 are also plotted for reference. Note that PGA values for MOD–1 and 2 in M4 are comparable to BA2008 (MOD-1 being closer to BA2008), and that PGA at stations s4 and s5 (outside theoretical Mach cone boundary) are within the one-sigma bounds of BA2008.

find that heterogeneities in source and medium collectively lead to lowered AFA from supershear ruptures within the Mach cone region.

6 DISCUSSION

The ground shaking computed by considering variations only in source parameters illustrates that slip and rise time variability slightly lowers the Mach wave coherence in near-fault distances (<10 km). Bizzarri *et al*. (2010) investigated the effects of rupture complexity on Mach waves, arising from heterogeneities in initial shear stress in their dynamic source models. They observed reduced peak ground velocity (PGV) due to variations of rupture speed and spatially less correlated slip velocity time histories. Similarly, we also note nearly 10 per cent decrease of PGA (due to $(H_{DT_r})_{avg}$) in close distances to the fault (<10 km). Some of the differences (in terms of PGA decrease) could arise between the two studies due to large slip-weakening distances used by Bizzarri *et al*. (2010), which may weaken the effects of stress heterogeneities. Their Fourier amplitude spectrum ratio between homogeneous and heterogeneous supershear rupture is nearly one. In contrast, we find a decline/increase of the average Fourier amplitudes for MOD-1/MOD-2 compared to U_{DT_r}, indicating a significant effect of source complexity on the spectral ratios at short distances (≤5 km).

Mach wave coherence beyond 10 km distance is reduced due to wavefield scattering from small-scale heterogeneities in the Earth. Bydlon & Dunham (2015) show that seismic scattering increases the duration of incoherent high frequencies, and hence elevates the root-mean-square acceleration, at least in 2-D. However, the Mach pulse is an extremely coherent high-frequency seismic wave, therefore,

Figure 14. Average Fourier amplitudes (AFA) as a function of frequency for the two horizontal components of ground motions for source models MOD–1 and 2 in medium M4, and source $U_{DT_rV_r}$ in the homogeneous medium. The AFA decreases with increasing distance from the fault for MOD–1 and 2 in M4 for frequencies above 1 Hz.

scattering lowers the PGA by redistributing the frequencies in the entire 3-D medium. Imperatori & Mai (2013) observe PGA decrease with increasing epicentral distance as a result of wavefield scattering for sub-Rayleigh ruptures. This supports our finding of medium scattering being responsible for the decline of Mach front coherence at large distances (>10 km) for supershear ruptures.

Ground-shaking levels in terms of PGA from supershear ruptures (in the Mach cone region) with both medium and source heterogeneities are in overall agreement with BA2008. The GMPEs inherently include intrinsic attenuation, whereas our simulations are elastic and we only approximately check for attenuation in a post-processing step (assuming constant *Q*); however, detailed consideration of anelastic attenuation may slightly reduce the shaking levels. Overall, we discover that the Mach wave coherence is slightly lowered by variations in slip and rise time in close distances to the fault (<10 km) and beyond this distance the wavefield scattering reduces the Mach wave coherence more dominantly resulting in PGAs from supershear ruptures comparable to BA2008. Therefore, our findings explain the observation of Bizzarri *et al*. (2010) that SA

were not elevated at stations that experienced Mach waves, compared to stations unaffected by the Mach pulse, during the 1979 Imperial Valley 1999 Izmit and 2002 Denali Fault earthquakes.

Our simulations are kinematic, in order to be able to precisely control the rupture complexity and the occurrence and spatial extent of supershear propagation. Thus, we do not attempt to study when and why supershear rupture happens. Additionally, Vyas *et al.* (2016) found that the ground-motion variability is higher than BA2008 in close distances to the fault (<20 km) at least for subshear ruptures considering heterogeneous rupture on the faults having geometric complexity. Therefore, dynamic simulations with large-scale fault segmentation and/or small-scale fault roughness are required, which may provide more insight into rupture heterogeneity and ground-motion complexity from supershear earthquakes. Fault segmentation may control rupture nucleation, rupture arrest and the seismic moment release for sub-Rayleigh speeds (Oglesby & Mai 2012; Aochi & Ulrich 2015). Fault roughness causes localized acceleration/deceleration of the rupture front due to local stress perturbations leading to high frequency radiation (Madariaga 1977; Dunham *et al*. 2011; Shi & Day 2013) that is important for engineering purposes and seismic-hazard estimation. Therefore, dynamic simulations with realistic variations in initial stress, friction on the fault, off-fault plasticity, 3-D medium heterogeneities, non-planar fault geometry and fault roughness are needed to gain a deeper understanding of the Mach wave coherence and resulting ground-shaking properties.

7 CONCLUSIONS

Ground-motion simulations reveal that Mach wave coherence is slightly diminished in the near field of earthquake rupture (distance < 10 km) by spatial variations of rise time and slip, while wavefield scattering reduces coherence more dominantly at larger distances (>10 km). Theory predicts larger ground-motion amplitudes and higher frequency content for supershear than sub-Rayleigh ruptures, whereas PGAs from our simulations (MOD-1 and MOD-2 in M4) are almost consistent with BA2008. We speculate that local supershear ruptures might be more common in nature than reported, but not easily detectable due to wavefield scattering and rupture complexity.

SUPPORTING INFORMATION

Supplementary data are available at *GJI* online.

Figure S1: (a) Slip heterogeneities (white contours depict rupture time in seconds), rise time and supershear rupture speed variations (MOD-2, MOD-3, MOD-4 and MOD-5) used for analysing effects on Mach wave coherence. The black star marks the hypocentre. (b) CCDF of the slip compared against log-normal (Lgn), exponential (Exp) and truncated exponential (Texp) distributions. (c–e) depicts correlations among rupture parameters (correlation coefficient is given in the bottom right of the plots and the red line shows linear least-squares fit).

Figure S2: Ground velocity (m s^{-1}) for fault parallel (FP), fault normal (FN) and vertical (Ver) components, comparing MOD-1 to the reference source U_{DT,V_r} at five stations (s1–s5, Fig. 1f). The-oretical arrivals from the epicentre of *P* and *S* waves (black bars) are also shown. Waveforms are aligned according to the theoretical *P*-wave arrival and normalized with respect to the absolute maxi-mum of the two sources for a given component (indicated in upper left corner). The *S*-Mach wave and Rayleigh–Mach wave are also marked.

Figure S3: Snapshots of the ground-velocity wavefield, for three components of motion computed using the reference source U_{DT,V_r} and MOD-1. The *S*-Mach wave (green dashed line) and Rayleigh–Mach wave (magenta dashed line) are marked to show their planar nature and orientation with respect to the fault. The Mach waves travel large distances from the fault without any attenuation.

Figure S4: PGA as a function of distance for 31 rupture mod-els depicts the effects of rupture heterogeneity on ground motions generated from supershear ruptures. The mean (circles) and stan-dard deviation (bars) of PGA are computed using stations at a given fault-perpendicular distance. The median (solid line) and one-sigma bounds (dashed lines) of PGA from BA2008 are shown for compar-ison. Note a clear trend for rupture models having heterogeneities only in rise time leading to equal/lower mean PGA compared to reference source.

Figure S5: Average Fourier amplitude (AFA) spectra as a function of frequency for the fault-parallel (FP) and fault-normal (FN) com-ponents of ground motion for six source models at different fault perpendicular distances (5, 20, 35 and 50 km). The AFA for rupture models having heterogeneities only in rise time is comparable or lower than reference source.

Figure S6: Ground velocity (m s^{-1}) for the fault-parallel (FP), fault-normal (FN) and Vertical (Ver) components, comparing two heterogeneous media M1 and M4 with the homogeneous medium at five stations (s1–s5, Fig. 1f). Theoretical *P*- and *S*-wave arrival times (for the homogeneous medium) are shown for reference. Waveforms are aligned according to the epicentral *P*-wave arrival time and normalized with respect to the absolute maximum of motion within

the three media for a given component (indicated in the upper left corner).

Figure S7: Snapshots in time of the velocity wavefield at the Earth's surface for three components of motion for media M1 ($a = 5.0$ km, $\sigma = 5$ per cent) and M4 ($a = 5.0$ km, $\sigma = 10$ per cent). As the Mach wave travels away from the fault, peak amplitudes decrease due to seismic scattering. Scattering effects, and hence amplitude reductions, are larger for medium with $\sigma = 10$ per cent.

Figure S8: Ground velocity (m s^{-1}) for the fault-parallel (FP), fault-normal (FN) and Vertical (Ver) components, comparing MOD-1 in M4 to $U_{DT_r V_r}$ in the homogeneous medium at five stations (s1–s5, Fig. 1f). The theoretical *P*- and *S*-wave arrival times in the homogeneous medium are shown for reference. Waveforms are aligned according to the epicentral *P*-arrival time and normalized with respect to absolute maximum of two signals for a given component (indicated in upper left corner).

Figure S9: Snapshots in time of the velocity wavefield at the Earth's surface for the three components of motion for source model MOD-1 in M4. Rupture parameters heterogeneities of MOD-1 lower the Mach wave amplitudes, which are then further reduced by scattering as the Mach wave travels away from the fault.
